FACTORS FOR CONVERTING INCH-POUND UNITS TO INTERNATIONAL SYSTEM (SI) UNITS

The following factors may be used to convert the inch-pound units used in this report to the International System of Units (SI).

<u>Inch-pound units</u>	<u>Multiply by</u>	<u>To obtain SI units</u>
<u>Area</u>		
square mile (mi ²)	2.590	square kilometer (km ²)
<u>Flow</u>		
cubic foot per second (ft ³ /s)	28.32	liter per second (L/s)
	.02832	cubic meter per second (m ³ /s)

GLOSSARY

Base flow - sustained or fair weather runoff. In most streams, base runoff is composed largely of groundwater effluent.

Discharge - the actual flow in a stream, whether or not subject to regulation, or underflow.

Diversion - the taking of water from a stream into a canal, pipeline, or other conduit.

Drainage area - the drainage area of a stream at a specified location is that area measured in a horizontal plane which is enclosed by a drainage divide.

Gaging station - a site at which systematic observations of stream flow are obtained. Gaging stations cited in this report provide continuous records.

Index station - the gaging station with which low-flow, partial-record sites are correlated. The discharge at index stations is not known to be affected by diversion or regulation.

Low flow - see "Base flow."

Low-flow partial-record station (LFPR) - a site where base-flow measurements are collected on a systematic basis over a period of years.

Low-flow year - a continuous period from April 1 to March 31, designated by the calendar year during which it starts.

MA7CD2 - minimum average 7-consecutive-day flow at a recurrence interval of 2 years.

MA7CD10 - minimum average 7-consecutive-day flow at a recurrence interval of 10 years.

Miscellaneous measurements - discharge measurements made at sites other than gaging stations or low-flow partial-record sites. In this report, probably made during base-flow conditions.

Period of record - the water years (October 1 to September 30) from which data on a given site are available.

Recurrence interval - the average time interval within which a flow of a given magnitude will recur once.

Regulation - artificial alteration of the natural flow of a stream to serve a specific purpose.

Water year - a continuous period from October 1 to September 30, designated by the calendar year in which it ends.

LOW-FLOW DATA AND FREQUENCY ANALYSIS OF
STREAMS IN NEW YORK EXCLUDING
NEW YORK CITY AND LONG ISLAND

By

Benjamin B. Eissler

ABSTRACT

Minimum average 7-day 2-year and 10-year discharges of 926 stream sites in New York excluding New York City and Long Island are listed. Also included are base-flow measurements at sites for which no statistics were computed. This report evaluates data collected before October 1975. Data are provided for gaging stations on 154 unregulated and 124 regulated streams, 648 low-flow partial-record stations, and 2,384 miscellaneous sites. All measurement-site locations are shown on maps. A short text explains the procedures used and the methods of calculation.

INTRODUCTION

The growth of population and industry in New York has increased the need for information on flows of streams. Knowledge of the magnitude and frequency of low flows is essential to planning and regulation of activities associated with surface-water resources. Examples of the uses of low-flow data include design of water-supply and waste-treatment facilities and evaluation of the impact of present or proposed facilities on the stream system. Regulatory agencies enforcing environmental decisions for preservation of wetlands and other "natural-state" areas also use low-flow information in monitoring designated areas.

Systematic use of low-flow partial-record stations began in the 1950's and increased in response to the drought of the early 1960's. About 30 percent of the measurement sites used in the current U.S. Geological Survey stream-gaging program were established during 1962-64.

This study was conducted from 1976-77 in cooperation with the New York State Department of Environmental Conservation.

Purpose and Scope

This study was undertaken to provide a compilation of data on the low flows of New York streams outside Long Island and the metropolitan area of New York City. The most frequently used type of low-flow data is the minimum 7-consecutive-day average discharge that is expected to be exceeded in all but one year in 2, or one year in 10. These statistical values are commonly referred to as the minimum average 7-day 2-year discharge (MA7CD2) and the minimum average 7-day 10-year discharge (MA7CD10).

The MA7CD2 and MA7CD10 were computed directly from daily flow records of 154 gaging stations on unregulated stream reaches, 8 of which are close to but outside the State of New York, and from the records of 124 gaging stations on regulated streams, 2 of which are outside the State boundary. Locations of sites are shown on plate 1; data for these sites are given in table 1 (at end of report).

Low-flow partial-record (LFPR) stations were established and operated to provide low-flow information where records of daily discharge were not available. MA7CD2 and MA7CD10 values are given for 648 LFPR stations in table 1; locations of these sites are shown in plate 2.

Miscellaneous measurements that do not belong in either of the above categories, but that were pertinent to this study, are listed in table 2 (at end of report); miscellaneous-site locations are shown in plate 1c.

Values of MA7CD2 and MA7CD10 at gaging-station sites were computed from records through water year 1975; data obtained since 1975 were used to compute these values for some LFPR stations and miscellaneous-measurement sites.

Some of the data in this report were obtained from the following publications (see "Selected References" for titles and publishers):

Ayer and Pauszek (1968)
Giese and Hobba (1970)
Harding and Gilbert (1968)
Ku, Randall, and MacNish (1975)
Vaupel (1967)
Waller and Ayer (1975)

Data from the above sources were reviewed and revised as necessary. The low-flow data from Harding and Gilbert (1968) are noted with the symbol "E" in table 1. They were computed by somewhat different procedures from those described herein and were not updated for this study.

Methods of Analysis

Gaging Stations

Low-flow characteristics of streams at gaging stations are determined from low-flow frequency curves as described in Riggs (1972). At least 10 years of record are needed for this determination.

The procedure used to determine the discharge/frequency relationship for 7-day low-flow values is as follows:

- (1) find the lowest mean 7-consecutive-day discharge in each low-flow year (year ending March 31);
- (2) arrange them in order of magnitude; and
- (3) compute the recurrence interval for each discharge by the plotting position formula

$$(n + 1)/m$$

where n is the number of items (years), and
 m is the order number obtained under (2).

The discharges are then plotted against recurrence interval on log-probability graph paper, and a smooth curve is drawn to fit the points. The discharge for the desired recurrence interval may be determined from this graph.

For this report, a computer program was used to determine discharge/frequency relationships for all sites having a complete record of daily discharges. The program mathematically fitted these discharge data from the gaging station to a log Pearson Type III distribution, plotted the data on a graph, then plotted the computed distribution curve. A sample of a printout from this program is shown in figure 1. Input data are the discharges during the lowest mean 7-day periods for each low-flow year, followed by statistical measures and probabilities and recurrence intervals with their discharges.

Twelve gaging stations included in this report were operated only during ice-free periods and thus provided no winter record. Comparison of these records with those of nearby stations indicate that the period of lowest 7-day average flow probably did not occur during the winter. Because the computer program could not process incomplete periods of record, low-flow characteristics for these sites were computed from graphs.

The only type of regulation considered in this report is that which affects low flow. For example, a gaging station downstream from a flood-control reservoir that has no permanent pool would not be noted as regulated because the reservoir would not affect low flows, whereas a reservoir with a permanent pool is considered regulated. Any diversion for water supply or other purposes, or any inflow such as sewage-treatment plant effluents, is also considered as regulation.

Analyses of regulated gaging stations are included in this report because they provide an indication of the flow patterns subsequent to start of regulation. Caution should be exercised when making projections concerning expected flow rates on regulated streams, for these can change as operating agencies vary their operating procedures. Where enough record is available, discharge/frequency relationships are shown for both regulated and unregulated periods. If it is known that the regulation pattern has changed, separate discharge/frequency relationships are shown for each known period of constant regulation. An example of this is station 01367500, Rondout Creek at Rosendale. The period 1926-44 was unregulated, emergency diversions were made from this stream from 1944-51, and from 1952-75, the station was regulated by Rondout Reservoir and is analyzed as a regulated station. The period 1944-51 was too short for analysis; therefore, no frequency assessment is included. A history of each stream's regulation is given in U.S. Geological Survey, "Water Resources Data for New York" (published annually), in the "Remarks" paragraph for each pertinent station.

The average standard error for unregulated gaging stations was computed as described in Hardison (1969) and shows an average standard error of the MA7CD10 for a gaging station with 10 years of record to be 22 percent, and for one with 50 years of record to be 9 percent. A tabulation of the average standard error for the MA7CD2 and MA7CD10, listed by major drainage basins, is shown in table 3 (p. 6).

The standard error for Mohawk and lower Hudson basins as well as Delaware and Susquehanna basins are shown together because the results for each were identical. Streams tributary to the Great Lakes (Lake Erie, Niagara River, and Lake Ontario) were grouped together because results appeared consistent and the data needed for separate analysis were not available.

Low-Flow Partial-Record (LFPR) Stations

Because it is not economical or practical to establish a gaging station at every site where low-flow data are needed, low-flow partial-record stations may be used to provide the needed data if satisfactory

index sites are available. At each LFPR site, at least five base-flow measurements were made over a period of at least 2 years. These measurements were then correlated with the concurrent daily mean flows at index stations, and the MA7CD2 and MA7CD10 were derived from graphs.

For a relevant correlation, the measurement at the LFPR site must be made under base-flow conditions, and the stream at the index stations must also be at base flow. During periods of scattered thunderstorms, it is difficult to judge whether base-flow conditions prevail when measurements are being made. If the index-station record shows a steady recession for at least 5 days prior to the date of measurement, it is reasonable to assume base flow at the index station. If base-flow conditions at the LFPR site were assumed but correlation with the index stations do not bear this out, the measurement was eliminated from the correlation.

An index station must (1) be unregulated, (2) be near enough to the LFPR site to receive similar patterns of precipitation, (3) have geologic and soil characteristics similar to those of the LFPR site, and (4) have a drainage area less than 10 times that of the LFPR site. Ideally, an index station should be on the same stream, or at least in the same drainage basin, as the site with which it is being correlated.

For this study, generally three but as many as five nearby index stations were used to estimate the low-flow characteristics of an LFPR site. Correlations that seemed consistent were averaged; LFPR sites that did not correlate with any index sites, presumably because of natural or manmade factors, were omitted from the analyses.

Table 3.--Average standard error of estimates of 7-day 2-year and 7-day 10-year low flows at gaging stations in major New York drainage basins [all values are in percent]

Basin	Period of record			
	MA7CD2		MA7CD10	
	10 yr	50 yr	10 yr	50 yr
Upper Hudson River	13	6	17	8
Mohawk and lower Hudson Rivers	21	8	25	11
Delaware and Susquehanna Rivers	17	8	24	10
Streams tributary to Great Lakes	15	5	21	9
Streams tributary to St. Lawrence River	8	3	12	5

To expedite the analyses described above and to minimize errors and bias, a computer program was used to plot the data and compute and plot a least-square fitted line through the data points. This correlation was examined for fit and outliers and was then modified as needed before intercepts of the MA7CD2 and MA7CD10 were assigned. An example of such a correlation is given in figure 2. The printout shows the statistical measures of the process; the X values are the MA7CD2 and MA7CD10 for the index station; the Y values are the computed corresponding discharges of the LFPR sites.

In table 1, the low-flow values of gaging stations and low-flow partial-record stations are arranged in the downstream order used in the U.S. Geological Survey Water-Supply Papers on surface-water supply of the United States (see "Selected References").

To determine the accuracy of the MA7CD2 and MA7CD10 estimates presented for LFPR sites, 25 stations were chosen at random, and a standard error for each was computed by the method described by Hardison and Moss (1972). This method considers both (1) the error in correlation of the LFPR with the index gaging station, and (2) the standard error of the low-flow frequency of the index gaging station. The standard error of the index sites ranged from 5 to 25 percent, with a median of 10 percent. The standard error of the LFPRs ranged from 10 percent to more than 100 percent, with a median of 23 percent.

Miscellaneous Sites

Data from sites where low-flow measurements were made but estimates of MA7CD2 and MA7CD10 could not be made are compiled in table 2; locations of these sites are shown on plate 3. Also included in table 2 and plate 3 are LFPR sites for which correlation failed because no representative index gaging station was available.

SUMMARY

The data in this report represent a summary of the information available on low flows in New York excluding New York City and Long Island. The maps show the locations and types of all measurement sites, and the tables provide information on size of drainage area and amount of data currently available. The data presented form a data base from which a study to develop techniques to predict minimum average 7-day 2-year and 7-day 10-year low flow rates at ungaged sites in New York could begin.
